# Low Complexity Normal Elements over Finite Fields of Characteristic Two 

Ariane M. Masuda, lucia Moura, Daniel Panario and David Thomson

#### Abstract

In this paper we extend previously known results on the complexities of normal elements. Using algorithms that exhaustively test field elements, we are able to provide the distribution of the complexity of normal elements for binary fields with degree extensions up to 39 . We also provide current results on the smallest known complexity for the remaining degree extensions up to 512 by using a combination of constructive theorems and known exact values. We give an algorithm to exhaustively search field elements by using Gray codes which allows us to reuse previous computations. We compare this with a standard method. We analyze this algorithm and show both experimentally and asymptotically that the Gray code optimization gives substantial savings. The total computation of the distribution of the complexity of normal elements for degrees up to 39 in our experiments allows us to draw several conjectures. In particular, our data provides remarkable evidence for the conjecture that the complexity of normal elements follows a normal distribution. Finally, we conjecture that there is no linear bound on the minimum complexity with respect to the degree of the extension.

Index Terms-Finite fields, normal elements, low complexity, Gray codes.

## I. Introduction

LET $\mathbb{F}_{q}$ be a finite field of order $q$, and let $\mathbb{F}_{q^{n}}$ be a finite extension of $\mathbb{F}_{q}$. A normal basis of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ is a basis of the form $N=\left\{\alpha, \alpha^{q}, \ldots, \alpha^{q^{n-1}}\right\}$ where $\alpha \in \mathbb{F}_{q^{n}}$. In this case, we say that $\alpha$ is a normal element of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$, or that $\alpha$ generates the normal basis $N$. The elements in $N$ are called the conjugates of $\alpha$. Normal bases exist in any finite extension of a finite field [14].

Let $\alpha_{i}=\alpha^{q^{i}}$ for $0 \leq i \leq n-1$, and let $T=\left(t_{i j}\right)$ be the $n \times n$ matrix given by

$$
\begin{equation*}
\alpha \alpha_{i}=\sum_{j=0}^{n-1} t_{i j} \alpha_{j}, \quad 0 \leq i \leq n-1, \quad t_{i j} \in \mathbb{F}_{q} . \tag{1}
\end{equation*}
$$

The complexity of the normal basis $N$, denoted by $c_{N}$, is the number of non-zero entries in $T$. Mullin, Onyszchuk, Vanstone and Wilson [18] proved that $c_{N} \geq 2 n-1$. The normal basis $N$ is said to be optimal when this lower bound is achieved, that is, when $c_{N}=2 n-1$. Optimal normal elements exist but not

[^0]in all finite fields (for instance, see [15, Chapter 3]). Optimal normal bases over finite fields were completely characterized by Gao and Lenstra [8].
The implementation of finite field arithmetic is highly required in several applications such as coding theory, cryptography and signal processing; see for example [16]. In particular, an important operation for these applications is exponentiation of elements in a finite field. It is well known that the use of normal bases yields efficient exponentiation in $\mathbb{F}_{2^{n}}$ [7], [23], including applications to hardware implementations [20]. Specifically, exponentiations to $2^{k}$, for any positive integer $k$, are just cyclic bit shifts. Moreover, when using normal bases the speed of multiplications over $\mathbb{F}_{2^{n}}$ depends directly on $c_{N}$ (see [5, Section 11.2.2]). Thus, it is important to use a normal basis in $\mathbb{F}_{2^{n}}$, for any given $n$, with the lowest possible complexity.
When no optimal normal basis exists, the problem of classifying low complexity normal bases still remains open. There is no proper definition of the term "low complexity". Ideally, one expects to have a complexity bounded by $k n$ for some small constant $k$. Young and Panario [26] conjecture that low complexity normal elements over finite fields of characteristic two with complexity up to $3 n$ only occur in finite fields with an optimal normal element. Wan and Zhou [25] extended part of the results in [26] for finite fields of odd characteristic.
For a better understanding of the behavior of the complexities of normal elements, tables summarizing the complexity distribution are important tools. In [15, Section 3.3], Jungnickel provides a table with minimum and maximum complexities of normal elements in $\mathbb{F}_{2^{n}}$, for each $n \leq 30$. In [15, Section 5.4], for $31 \leq n \leq 60$, he provides a table due to Geiselmann [13] with the lowest complexities found via free polynomials. In this paper, we present the distribution of the complexity of normal elements for $n \leq 39$. We gather, for each $n$ in this range, the frequency of each possible complexity value. We give summary tables with minimum, maximum, average and variance values for the complexities of normal elements and self-dual normal elements in $\mathbb{F}_{2^{n}}$. We do a statistical fit of the frequency data, for each $n \leq 39$, that clearly suggests that the complexities of normal elements in $\mathbb{F}_{2^{n}}$ follow a normal distribution. Our data is obtained via an exhaustive search in $\mathbb{F}_{2^{n}}$ which is substantially sped up by visiting the finite field elements in a Gray code order. We also extend the table of the smallest known complexities for other practical values of interest ( $40 \leq n \leq 512$ ), using a combination of previously known results and random search.

This paper is organized as follows. In Section II, we give a brief survey of known results about normal elements that are relevant and used in our research. In Section III, we describe
and analyze the algorithms that we use for the exhaustive complexity computations. Our asymptotic analysis shows that using a Gray code order, instead of an arbitrary order, allows a $21.05 \%$ reduction on the running time. Tables and conjectures are given in Section IV.

## II. Previous results

We start with a criterion, due to Davenport, that we use to determine whether an element is normal or not.

Theorem 1: [15, Theorem 3.1.8] Let $\alpha$ be an element in $\mathbb{F}_{q^{n}}$. Then $\alpha$ is a normal element of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ if and only if the polynomials $x^{n}-1$ and

$$
\alpha^{q^{n-1}} x^{n-1}+\cdots+\alpha^{q} x+\alpha
$$

in $\mathbb{F}_{q^{n}}[x]$ are relatively prime.
The number of normal elements was established by Ore.
Theorem 2: [15, Theorem 3.1.5] Let $q$ be a power of the prime $p$, let $n$ be a positive integer and write $n=p^{a} m$, where $p$ does not divide $m$. Then the number of normal bases of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ equals

$$
\frac{1}{n} \Phi_{q}\left(x^{n}-1\right)=\frac{q^{n}}{n} \prod_{d \mid m}\left(1-q^{-o_{d}(q)}\right)^{\phi(d) / o_{d}(q)}
$$

where $\Phi_{q}(f)$ is the number of polynomials in $\mathbb{F}_{q}[x]$ of degree smaller than the degree of $f$ which are relatively prime to $f$, $o_{n}(a)$ is the order of $a$ modulo $n$, and $\phi(d)$ is the number of positive integers smaller than $d$ that are relatively prime to $d$.

Several authors have provided lower and upper bounds for the number of normal bases of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$. Here, we present Gao and Panario's upper bound [9, Theorem 3.4]:

$$
\begin{equation*}
\frac{1}{n} \Phi_{q}\left(x^{n}-1\right) \leq \frac{q^{n}}{e^{\gamma-c_{q}} n \sqrt{1+\log _{q} n}} \tag{2}
\end{equation*}
$$

where $\gamma=0.577216 \ldots$ is Euler's constant and $c_{q}=$ $q /((q-1)(\sqrt{q}-1))$; see also [6]. Von zur Gathen and Giesbrecht [12] showed that the probability that an arbitrary element in $\mathbb{F}_{q^{n}}$ forms a normal basis is larger than $1 /\left(16 \log _{q} n\right)$.

Specific criteria to identify optimal normal elements are provided by Mullin, Onyszchuk, Vanstone and Wilson [18]. As a consequence of these criteria, given $n$, it is simple to determine whether there exists an optimal normal basis in $\mathbb{F}_{q^{n}}$ or not. When $q=2$, a list with all such values of $n$ up to 1300 can be found in [15, Table 3.1]. There is also a list of all complexities of normal bases for $\mathbb{F}_{2^{n}}$ with $n$ up to 30 in [15, Table 3.2]. Using our algorithms, we extend this table for $n$ up to 39 (Table IV). For $n$ from 40 to 512, we give the smallest complexity found using different methods from the literature (Table V). The details will be explained later; we now present some results that are used to compute these tables.

We present a theorem using generalized Gauss periods to construct normal bases with known complexities. This theorem was shown for extensions $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$ by Ash, Blake and Vanstone [1], and for general $q$ independently by Beth, Geiselmann and Meyer [2].

Theorem 3: [1], [2] Let $q$ be a prime or a prime power, and let $n$ and $k$ be positive integers such that $n k+1$ is a prime
not dividing $q$. Let $\beta$ be a primitive $(n k+1)$ th root of unity in $\mathbb{F}_{q^{n k}}$. Suppose that $\operatorname{gcd}(n k / e, n)=1$ where $e$ is the order of $q$ modulo $n k+1$. Then, for any primitive $k$ th root of unity $\tau$ in $\mathbb{Z}_{n k+1}$, the element

$$
\alpha=\sum_{i=0}^{k-1} \beta^{\tau^{i}}
$$

generates a normal basis of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ with complexity at most $(k+1) n-k$, and at most $k n-1$ if $k \equiv 0(\bmod p)$, where $p$ is the characteristic of $\mathbb{F}_{q}$.
This construction defines optimal normal elements for $k=1$ for all $q$, and for $k=2$ and $q=2$. These elements generate the so-called Type I and Type II optimal normal bases, respectively. In [8], Gao and Lenstra prove that these elements characterize all optimal normal bases over finite fields. In general, the exact complexity of a basis constructed using Theorem 3 is difficult to analyze. For $q=2$ we have the following special cases.

Theorem 4: [1] Let $q=2$. Then the normal basis $N$ generated by $\alpha$ as constructed in Theorem 3 has complexity
$c_{N}= \begin{cases}4 n-7 & \text { if } k=3,4 \text { and } n>1 ; \\ 6 n-21 & \text { if } k=5 \text { and } n>2 \text { or } k=6 \text { and } n>12 ; \\ 8 n-43 & \text { if } k=7 \text { and } n>6 .\end{cases}$
The following recursive construction allows us to cover more finite fields in Table V.

Theorem 5: [15, Theorem 3.3.13] Let $\alpha$ and $\beta$ generate normal bases $A$ and $B$ for $\mathbb{F}_{q^{m}}$ and $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$, respectively. Assume that $m$ and $n$ are coprime and put $\gamma:=\alpha \beta$. Then $\gamma$ generates a normal basis $N$ for $\mathbb{F}_{q^{m n}}$ over $\mathbb{F}_{q}$ and $c_{N}=c_{A} c_{B}$. Furthermore, if $\alpha$ and $\beta$ both generate optimal normal bases, then $\gamma$ has complexity $c_{N}=4 m n-2 m-2 n+1$.
As a consequence (see [15, Corollary 3.3.15]), if we let the complexity of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ be

$$
C_{q}(n):=\min \left\{c_{N}: N \text { is a normal basis for } \mathbb{F}_{q^{n}} \text { over } \mathbb{F}_{q}\right\}
$$

and if $m$ and $n$ are relatively prime, then $C_{q}(m n) \leq$ $C_{q}(m) C_{q}(n)$.

Next we give a class of theorems which allows us to construct even more low complexity normal bases in subfields of finite fields containing optimal normal bases. To do this, we first define the trace of an element $\alpha \in \mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q^{m}}$, where $n=k m$, by $\operatorname{Tr}_{q^{n} / q^{m}}(\alpha)=\alpha+\alpha^{q^{m}}+\cdots+\alpha^{q^{(k-1) m}}$. We present the statement of the theorem for the $q$ even and Type I case, and give a table of results for both Type I and Type II cases (Table I). There are analogous results for the $q$ odd case, and for the dual bases of the given constructions, however in this paper we focus only on finite fields of even characteristic.

Theorem 6: [4] Let $\alpha \in \mathbb{F}_{2^{n}}$ generate an optimal normal basis of Type I of $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}, n>2$, and let $\beta=$ $\operatorname{Tr}_{2^{n} / 2^{m}}(\alpha) \in \mathbb{F}_{2^{m}}$ with $m=n / k$ and $k \leq m$. Then, an upper bound for the complexity of the normal basis of $\mathbb{F}_{2^{m}}$ over $\mathbb{F}_{2}$ generated by $\beta$ is $(k+1) m-3 k+2$ if $m$ is even and $k$ is odd, or $k m-k+1$ otherwise.

A table containing optimal normal elements, the number of normal bases, the minimum and the maximum complexity in

TABLE I
SUMMARY OF BEST-KNOWN LOW COMPLEXITIES FOR $\mathbb{F}_{2^{m}} \subseteq \mathbb{F}_{2^{n}}$ OBTAINED BY TRACES, WHERE $m=n / k$.

|  | Type I | Type II |
| :--- | :--- | :--- |
| $m$ odd | $k m-k+1$ | $2 k m-2 k+1$ |
| $m$ even, $k$ odd | $(k+1) m-3 k+2$ | for all $m$ |
| $m$ even, $k$ even | $k m-k+1$ |  |

$\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$ for $n \leq 30$ was presented by Mullin, Onyszchuk, Vanstone and Wilson [18]. For $n \leq 27$, this information was obtained through a computer search. For $n=28,29$ and 30 , no computer search was performed by these authors due to the computational complexity and the observation that these fields contain optimal normal bases.

We focus now on self-dual normal bases. Self-dual normal bases form a special class of normal bases that have also been used in finite field implementations [24]. Suppose $A=\left\{\alpha_{0}, \alpha_{1}, \ldots, \alpha_{n-1}\right\}$ is a basis of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$. A dual basis $\left\{\beta_{0}, \beta_{1}, \ldots, \beta_{n-1}\right\}$ of $A$ is defined, for $0 \leq i, j, \leq n$, by

$$
\operatorname{Tr}\left(\alpha_{i} \beta_{j}\right)= \begin{cases}1, & \text { if } i=j \\ 0, & \text { if } i \neq j\end{cases}
$$

The basis $A$ is called self-dual if $\beta_{i}=\alpha_{i}$ for all $i, 0 \leq i \leq$ $n-1$. It is well known that, for each basis $\left\{\alpha_{0}, \alpha_{1}, \ldots, \alpha_{n-1}\right\}$ of $\mathbb{F}_{q^{n}}$, there exists a unique dual basis. Also, the dual of a normal basis is always normal. The following result provides a simple way of recognizing self-dual normal bases.
Theorem 7: [15, Corollary 5.1.3] Let $\alpha$ be a generator for a normal basis $B$ of $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$, and $T=\left(t_{i j}\right)$ be the matrix defined in (1). Then $B$ is self-dual if and only if $T$ is symmetric.

A self-dual normal basis of $\mathbb{F}_{q^{n}}$ over $\mathbb{F}_{q}$ exists if and only if either $q$ is even and $n$ is not a multiple of 4 or both $q$ and $n$ are odd (see [15, Theorem 5.2.1]). As a consequence, there is no self dual normal basis of $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$ if 4 divides $n$. If $n \equiv 2(\bmod 4)$, the next two results show how to obtain a self-dual normal basis over $\mathbb{F}_{2^{n}}$, provided that a basis of the same type is given, and how their complexities are related.

Theorem 8: [15, Corollary 5.4.3] Let $\alpha \in \mathbb{F}_{2^{n}}$, where $n$ is even, and put $\gamma:=1+\alpha$. Then $\alpha$ generates a self-dual normal basis if and only if $\gamma$ does.

Theorem 9: [15, Theorem 5.4.4] Let $\alpha$ generate a selfdual normal basis $B$ for $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$, and assume that $n$ is even. Put $\gamma:=1+\alpha$, and let $B^{C}$ be the self-dual normal basis generated by $\gamma$. Then the complexities of $B$ and $B^{C}$ are related as follows

$$
C_{B^{C}}=n^{2}-3 n+8-C_{B} .
$$

For $n \equiv 2(\bmod 4)$, the average complexity of a self-dual normal basis for $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$ is $\frac{1}{2}\left(n^{2}-3 n+8\right)$ (see [15, Corollary 5.4.5]). Also, if $C_{B}$ is the complexity of a self-dual normal basis $B$ then

$$
2 n-1 \leq C_{B} \leq n^{2}-5 n+9
$$

Equality holds in one of these bounds if and only if either $B$ or $B^{C}$ is optimal; in this case, $2 n+1$ is prime and 2 is a primitive root modulo $2 n+1$ (see [15, Theorem 5.4.6]).

## III. AlGORITHMS FOR COMPUTING THE COMPLEXITY DISTRIBUTION OF NORMAL ELEMENTS

In this section, we describe and analyze two variants of an exhaustive algorithm for computing the complexity of each normal element in $\mathbb{F}_{q^{n}}$. Algorithm StandardNCD (for "Standard Normal Complexity Distribution") is the simplest variant. Algorithm GrayCodeNCD (for "Gray Code Normal Complexity Distribution"), the second variant, uses Gray codes in order to efficiently update the current finite field element and its conjugates. We use basic operations in $\mathbb{F}_{q}$ as our time complexity measure. Then we show that asymptotically the Gray code variant reduces the time complexity of the standard algorithm by $21.05 \%$. We present the algorithms and their analyses for $q=2$. Their extensions to general $q$ are straightforward.

## A. Description of the algorithms

We now describe Algorithm StandardNCD; its pseudocode appears in Fig. 1. At each step, we compute $\alpha \in \mathbb{F}_{2^{n}}$, represented as a polynomial over $\mathbb{F}_{2}$ with coefficients stored in the tuple $\alpha_{\text {coeff }}=\left[a_{n-1}, \ldots, a_{0}\right]$. We define variables $\alpha_{j}=\alpha^{2^{j}}, j=0,1, \ldots, n-1$, to store $\alpha$ and its conjugates. The main loop runs through $\alpha \in \mathbb{F}_{2^{n}}^{*}$, updating the tuple $\alpha_{\text {coeff }}$ with the next binary tuple, using an arbitrary order computed via the function NextTuple () in line 12.

Each field element $\alpha$ is processed in lines 6-11. Since conjugates form an equivalence class for the computation of the complexity of normal elements, we only compute the complexity for one canonical representative of the normal basis. We stipulate that $\alpha$ is canonical if and only if $\alpha$ is the (unique) minimum element among $\left\{\alpha^{2^{j}}\right\}_{j=0}^{n-1}$, when using the lexicographical ordering of the coefficients of their polynomial representations. For a canonical element $\alpha$, we check if it is normal using the procedure IsNormal which employs a gcd test based on Theorem 1. If $\alpha$ is normal, then we calculate its complexity via the procedure CalculateComplexity, which is an implementation of the complexity definition; see (1). This amounts to solving an $n \times n$ system of equations with coefficients in $\mathbb{F}_{2}$. Since the only difference between these systems of equations are their right-hand sides, we calculate the inverse of the matrix $P$ associated with the system and then apply $n$ multiplications of $P^{-1}$ by vectors in $\mathbb{F}_{2}^{n}$.

The values of $\alpha$ and its conjugates are updated in lines 1215. Algorithm StandardNCD does a straightforward update, while Algorithm GrayCodeNCD employs a more efficient update that uses a Gray code.
A Gray code is an ordering of the $2^{n}$ binary vectors of length $n$ such that any two consecutive vectors have Hamming distance equal to 1 , i.e. any two consecutive vectors differ in a unique position $k$. Gray codes are well studied (see [21]) and they exist for every $n$. In particular, we can build a Gray code in which the first vector is the zero vector, and each next vector can be computed in time linear with $n$. In the GrayCodeNCD algorithm, this computation is done by calling the function NextGrayTuple() in line 12.

Now we describe how Gray codes are used to update $\alpha$. Let $\alpha^{\prime}$ be the field element in the previous iteration and
$\alpha$ be the field element in the current iteration, represented as polynomials over $\mathbb{F}_{2}$. Since their polynomial coefficients correspond to successive tuples in a Gray code, we have $\alpha=\alpha^{\prime}+x^{k}$, for some $k \in\{0,1, \ldots, n-1\}$. Therefore, $\alpha^{2^{j}}=\left(\alpha^{\prime}+x^{k}\right)^{2^{j}}=\left(\alpha^{\prime}\right)^{2^{j}}+\left(x^{k}\right)^{2^{j}}$. In lines 1-2 of the algorithm GrayCodeNCD, the values $e_{i}^{j}=\left(x^{i}\right)^{2^{j}}$ are precomputed, and used in line 15 for updating $\alpha$. This reduces the computation in lines $14-15$ from $n-1$ squarings, as in the standard algorithm, to $n$ additions in the Gray code variant.

We recall from Theorem 7 that a self-dual normal basis has a symmetric multiplication table. So, in order to adapt the given algorithms to search exclusively for self-dual normal elements, we alter the CalculateComplexity procedure to solve for $t_{i j}$ row-by-row (i.e. solving the system up to $n$ times), and check the non-diagonal elements (up to the index of the calculated row) for symmetry. If this follows to completion, the normal element is self-dual, and the complexity is stored. We call this algorithm SelfDualNCD.

## B. Analyses of the algorithms

In this section, we analyze the amortized worst-case running time per finite field element, which we call $T S(n)$ and $T G(n)$, for standard and Gray code variants, respectively. Therefore, the total running time of each algorithm will be at most $2^{n} T S(n)$ and $2^{n} T G(n)$, respectively. We do our analysis in terms of $M(n)$, the number of basic operations in $\mathbb{F}_{2}$ used in a multiplication of polynomials of degree smaller than $n$ over $\mathbb{F}_{2}$. We then compute the savings in running time given by the Gray code variant with respect to the standard one.

For the multiplication of polynomials of degree $n$ over $\mathbb{F}_{2}$, we consider the classical method in which $M(n)=2 n^{2}+$ $O(n)$ (see Section 2.3 in [10]), and Karatsuba's method in which $M(n) \leq 9 n^{\log _{2} 3} \leq n^{1.59}$ (see Section 8.1 in [10]). In addition, we observe that a multiplication in $\mathbb{F}_{2^{n}}$ corresponds to one multiplication of polynomials of degree at most $n-1$ followed by a modular reduction by the polynomial defining the extension $\mathbb{F}_{2^{n}}$. This multiplication in $\mathbb{F}_{2^{n}}$ costs $3 M(n)+$ $O(n)$ operations in $\mathbb{F}_{2}$ (see Section 9.7 in [10]).

We first analyze the steps that are common to both algorithms. The canonicity test in line 6 can be done in $O\left(n^{2}\right)$ comparisons in $\mathbb{F}_{2}$. Procedure IsNormal called in line 7 is only run for $1 / n$ of the field elements. Each time it is run, it involves the computation of a gcd between polynomials of degrees $n-1$ and $n$ over $\mathbb{F}_{2^{n}}$ (see Theorem 1). This gcd can be computed, using the Euclidean algorithm, in at most $n+1$ inversions and $2.5 n^{2}+O(n)$ additions and multiplications in $\mathbb{F}_{2^{n}}$ (see Section 3.3 in [10]). As we have seen, multiplications in $\mathbb{F}_{2^{n}}$ can be executed in $3 M(n)+O(n)$ operations in $\mathbb{F}_{2}$, while additions require $O(n)$. Since $n+1$ inversions in $\mathbb{F}_{2^{n}}$ can be computed in $O\left(n^{3}\right)$ operations in $\mathbb{F}_{2}$, line 7 can be computed in time $7.5 n^{2} M(n)+O\left(n^{3}\right)$ operations in $\mathbb{F}_{2}$. Therefore, the amortized time for line 7 is $7.5 n M(n)+O\left(n^{2}\right)$.

Lines 8-9 are only executed $\Phi_{2}\left(x^{n}-1\right) / n$ times in total, since the number of normal elements is $\Phi_{2}\left(x^{n}-\right.$ 1) by Theorem 2. Each time these lines are run, algorithm CalculateComplexity is executed. For this algorithm, steps 1-2 take $O(n M(n))$, steps 3-7 and 10 take
$O\left(n^{2}\right)$ and steps 8-9 take $O\left(n^{3}\right)$. So, the running time of CalculateComplexity is $O\left(n M(n)+n^{3}\right)=O\left(n^{3}\right)$. Thus, the amortized cost for lines 8-9 in both main algorithms is $O\left(n^{3} \Phi_{2}\left(x^{n}-1\right) /\left(n 2^{n}\right)\right)$, which, by the upper bound in (2), is $O\left(n^{2} / \sqrt{\log n}\right)$.

The iterations of each algorithm differ in the updates performed in lines $12-15$. For the standard algorithm, the cost of these lines is dominated by $n-1$ squarings of an element in $\mathbb{F}_{2^{n}}$. Each of these operations can be done by squaring a polynomial over $\mathbb{F}_{2}$ of degree smaller than $n$ followed by a modular reduction by a polynomial of degree $n$. The cost of each squaring in $\mathbb{F}_{2^{n}}$ is then dominated by the modular reduction at a cost of $2 M(n)+O(n)$. Thus, lines 12-15 for the standard algorithm cost $2 n M(n)+O\left(n^{2}\right)$ operations in $\mathbb{F}_{2}$. On the other hand, for the Gray code algorithm, the cost of lines $12-15$ is dominated by $n$ additions of polynomials of degree smaller than $n$ over $\mathbb{F}_{2}$, which can be done in time $O\left(n^{2}\right)$.
Combining the above analyses for the steps of each algorithm, we get

$$
\begin{aligned}
T S(n) & =7.5 n M(n)+2 n M(n)+O\left(n^{2}\right) \\
& =9.5 n M(n)+O\left(n^{2}\right) \\
T G(n) & =7.5 n M(n)+O\left(n^{2}\right) .
\end{aligned}
$$

Using the above equations, we conclude that the Gray code variant gives (asymptotically) savings of (9.5 7.5) $n M(n) / 9.5 n M(n) \approx 21.05 \%$, independently of the multiplication method used.
Finally, in Table II, we give asymptotic estimates of $T S(n)$ and $T G(n)$ for specific values of $M(n)$, using classical and Karatsuba's multiplication methods. There are other multiplication methods with smaller asymptotic running times, but these methods are less efficient for smaller $n$ 's (see [11, Section 7]). The cross-over happens for $n$ 's much larger than the ranges our algorithms could be applied, since iterations are repeated $2^{n}$ times.

TABLE II
Running times (PER FIELD ELEMENT) USING DIFFERENT MULTIPLICATION METHODS.

| Method | Karatsuba's | Classical |
| :--- | :--- | :--- |
| $M(n)$ | $9 n^{\log _{2} 3} \leq 9 n^{1.59}$ | $2 n^{2}$ |
| $T S(n)$ | $85.5 n^{1+\log _{2} 3}+O\left(n^{2}\right)$ | $19 n^{3}+O\left(n^{2}\right)$ |
| $T G(n)$ | $67.5 n^{1+\log _{2} 3}+O\left(n^{2}\right)$ | $15 n^{3}+O\left(n^{2}\right)$ |

## IV. RESULTS AND CONJECTURES

Table III gives a comparative runtime analysis of all the algorithms, and Table IV outlines the main results found in this experiment using the GrayCodeNCD and SelfDualNCD algorithms for $n \leq 39$. In Table V we give the best known complexities found for $40 \leq n \leq 512$ using several sources from the literature. These results are analyzed, and conjectures are presented based on the findings.
The experiments were performed on individual Pentium IV 3.0 GHz systems with 1.5 GB of DDR RAM. The operating

system was Red Hat Linux Enterprise Edition kernel 2.6.934.EL. We use C++, compiled using g++ 3.4.3, for all programming tasks. For arithmetic performed over $\mathbb{F}_{2}$, Shoup's NTL package version 5.3.2 was used [22], specifically taking advantage of the optimized binary arithmetic "GF2" libraries.

## A. Exhaustive search for $n \leq 39$

Table III gives the CPU User-time for the StandardNCD, GrayCodeNCD, and the SelfDualNCD algorithms, measured in seconds. We observe from Table III that the running time of the SelfDualNCD algorithm is approximately ten percent faster than the GrayCodeNCD algorithm running time, though no analysis of this algorithm is presented. Moreover, a comparison of the running time per element shows an improvement in the GrayCodeNCD algorithm over the StandardNCD ranging from $26 \%$ to $35 \%$ for $20 \leq n \leq 30$. We also include Fig. 2 for graphical comparison.

Table IV shows findings on the complexity of normal elements for every finite field $\mathbb{F}_{2^{n}}$ with $n \leq 39$, computed with the implementation of the GrayCodeNCD algorithm. This includes the number of normal bases found $\left(\left(\Phi_{2}\left(x^{n}-1\right)\right) / n\right)$, the smallest and the largest complexities ( $m_{c_{N}}, M_{c_{N}}$ ), average complexity, variance and standard deviation $\left(A v g_{c_{N}}, \operatorname{Var}_{c_{N}}\right.$, $\sigma_{c_{N}}$, and the smallest and the largest complexities for selfdual normal elements ( $m_{c_{N}}^{\prime}, M_{c_{N}}^{\prime}$ ). Due to the time limitations, no search was performed for self-dual normal elements for $n \geq 37$. The optimal normal bases found are in agreement with the theorem of Gao and Lenstra [8] that characterizes for which fields optimal normal bases exist.

Fig. 2. Average runtime per element for two exhaustive algorithms.

## B. Lowest found complexities for $40 \leq n \leq 512$

Table V is devoted to the cases when $40 \leq n \leq 512$. For these values of $n$, no self-dual testing has been performed. When an optimal normal element is known not to exist, we show the lowest complexity found by using known methods from the literature. In the first method considered, we check the conditions of Theorem 3 for values of $k$ in the range established in the theorem. We are given exact complexities by Theorem 4. In the second method, we apply Theorem 5 which allows us to combine two complexities previously computed. In the third method, we apply Theorem 6 which allows us to find low complexity normal elements from larger fields containing an optimal normal basis. The final method is based on a random search, which starts with a random finite field element, and randomly flips one of its polynomial coefficients a prescribed number of times, keeping the normal element found with lowest complexity. If Theorem 3 gives the lowest complexity then we indicate in the "Property" column of Table V which $k$ value satisfies the conditions of the theorem. If Theorem 5 gives the lowest complexity, we indicate the coprime factorization of $n$ that gives the low complexity. If the method of Theorem 6 achieves the lowest complexity, we note in the "Property" column which type of normal basis and which value of $k$ is used. Theorem 5 does not apply for $n$ prime or prime-power, and in the absence of an optimal basis for degree $n$ or for a multiple of degree $n$, the random search is required. However, random search yields quite large smallest found complexities, and so appears only for few values of $n$. We observe that the smallest complexity found is not necessarily the minimum complexity possible in the field and for this reason the best found complexity is denoted as $\min c_{N}$.

TABLE IV
Statistics on the complexity of normal elements obtained using the graycodencd and the selfdualncd algorithms.

## C. Conjectures

To examine the distribution of normal bases of $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$, in Fig. 3 we plot the number of normal bases found against their complexity. In each case, we observe a Gaussian shaped curve. This leads to the following conjecture.

Conjecture 1: The number of normal bases for $\mathbb{F}_{2^{n}}$ over $\mathbb{F}_{2}$ is normally distributed with respect to their complexities.

This conjecture is verified for $n \leq 39$ by running the Shapiro-Wilk normality test [19] on the results of the GrayCodeNCD experiments and, for $15 \leq n \leq 39$, is guaranteed with over $99.9 \%$ certainty. As a consequence of this conjecture, although probabilistic algorithms to find normal elements exist [12], these will not give low complexity normal elements. For efficient computation, new searching methods for normal elements must be developed.

Finding the general form of the distribution curve requires calculating the average complexity and the variance. Alternatively, an enveloping curve requires bounds (as functions of $n$ ) to find the averages and variances of the complexities. This is the motivation for the Conjectures 2 and 3, which suggest upper bounds on the average and variance of the complexities of normal bases.

The data lends itself to the following conjecture on a bound for the average complexity of normal elements.

Conjecture 2: The average complexity of normal elements in a finite field $\mathbb{F}_{q^{n}}$ with $n \geq 8$ has an upper bound of $\left(n^{2}-\right.$ $n+3) / 2$.

This conjecture is based upon the data found using the GrayCodeNCD algorithm, and observing the symmetry of the Gaussian curve conjectured previously. This is very close to half of the largest possible complexity $n^{2}-n$, which is

Fig. 3. Sample distributions of complexity of (a) normal elements and (b) self-dual normal elements.
always even, so the extra factor of adding 3 in the numerator accounts for any decimal places calculated in the average. This conjectured bound is quite tight for many values of $n \leq 39$, and only for $n=14,23,25$ the numerator requires a constant term of 3 rather than 2 .

Conjecture 3: For sufficiently large $n$ the variance of complexities of normal bases is bounded above by $n^{2} / 2$.

This conjecture comes from the side-by-side comparison in Table IV of the average and variance of the complexities. For this data $n \geq 19$ suffices. The variance and the average complexity are quite similar, which implies that there could probably be a stronger conjecture here, since this conjecture is loose in comparison to the one on the average complexity.

We recall that the average complexity of self-dual normal elements is given in Theorem 9, so the next step would naturally be to conjecture on the variance of the complexity of self-dual normal elements. However, since there are very few self-dual normal bases for $n \leq 36$ more experiments are required to give sufficient data to support any such conjecture.

The following argument leads to our final conjecture. Let us assume that the above conjectures on the average and variance of complexities of all normal elements in a finite field (i.e, not restricted to self-dual normal elements) hold. Moreover, let us consider the following problem: is there some constant $k$ such that the minimum complexity element in a finite field $\mathbb{F}_{2^{n}}$ is bounded above by $k n$ ? We observe that the probability of finding a normal element of complexity $c_{N} \leq k n$ is analogous to finding the density under the normalized curve as follows, $P\left(c_{N} \leq k n\right)=P[Z \leq(k n-\mu) / \sigma]$. A low complexity is analogous to a low Z-score on the normalized curve. Given that, by our conjectures, $\mu=\left(n^{2}-n+3\right) / 2$ and $\sigma^{2}=n^{2} / 2$, calculating the Z -score of $k n$ gives $\frac{k n-\frac{n^{2}-n+3}{2}}{n / \sqrt{2}}$. We observe now that if $k$ is a constant, then the Z-score becomes infinitely small. Relating this to the complexity distribution, this implies that the upper bound on the minimum complexity vanishes, which is a contradiction since the minimum possible complexity is $2 n-1$.

Conjecture 4: There is no constant $k$ such that the complex-
ity $C_{n}$ of $\mathbb{F}_{2^{n}}$ is bounded above by $k n$ for all $n$. Furthermore, if the average and variance of the complexities of all normal elements in $\mathbb{F}_{2^{n}}$ are both of order $n^{2}$, then $C_{n}$ is also of order $n^{2}$.

Our final observation concerns the distribution of the normal elements themselves. To achieve results for $36 \leq n \leq 39$ we distributed the computation across many processors by letting each processor deal with a range of field elements that were consecutive in the Gray code order. This divided our time linearly with the number of processors used. For example, the estimated run time of $n=39$ was 8 months using a single processor, but we were able to complete the simulation in just under 3 weeks using 13 processors. Furthermore, we observed that there were large blocks along the run of the Gray code in which there were no lexicographically canonical normal elements found. This is an interesting topic for future research about the existence of normal elements with prescribed coefficients.

## Acknowledgment

We would like to thank the two anonymous reviewers for their careful review of this paper, and for all of their insightful comments and suggestions.

Ariane M. Masuda received her Bachelor's degree in Mathematics from the Federal University of Paraná, her Master's degree in Mathematics from the Fluminense Federal University, and her Ph.D. in Mathematics from Carleton University. She is currently an NSERC postdoctoral fellow at the University of Ottawa. Her research interests include algebra, number theory, cryptography, and coding theory.

Lucia Moura was born in Brazil, where she completed her Bachelor's and Master's degrees in Computer Science, at the University of São Paulo. She completed her Ph.D. in Computer Science at the University of Toronto in 1999, and joined the School of Information Technology and Engineering of the University of Ottawa (Canada) in 2000, where she is currently an Associate Professor. Her main research areas are algorithms and combinatorics, with special interest in combinatorial algorithms, combinatorial designs and their applications.

Daniel Panario was born in Uruguay where he studied Mathematics and Computer Science. He received a M.Sc. degree from the University of São Paulo (Brazil) and a Ph.D. from the University of Toronto (Canada). He is an Associate Professor at Carleton University in Ottawa (Canada). His main research interests are in finite fields and applications, and in analysis of algorithms.

David Thomson was raised in the Ottawa, Canada area and completed his B.Math in 2006 and M.Sc. in Mathematics in 2007 from Carleton University (Canada). He is currently a Ph.D. student in the Department of Electrical and Computer Engineering at the University of Waterloo (Canada). His research interests include finite fields and their applications, and in cryptography and security.
